Acknowledgments

First and foremost I thank my wife, Lucy, for her love and support and for her professional expertise in editing the manuscript for clarity. I thank my daughter Elizabeth and son-in-law Michael for their love and support. I thank my colleague Michael Vogeley, who kindly read the entire manuscript and offered his excellent comments and additions, Bob Vanderbei and Li-Xin Li for assistance with diagrams, and Zachary Slepian, Matias Zaldarriaga, Nima Arkani-Hamed, and Andrew Hamilton for their helpful comments. I thank my agent Jeff Kleinman who is always a pleasure to work with, and my wonderful editor at Princeton University Press, Ingrid Gnerlich, and her assistant, Eric Henney. I thank my production editor, Brigitte Pelner, my copyeditor, Linda Thompson, and my illustration manager, Dimitri Karetnikov for their expert help.

It is a pleasure to acknowledge the many colleagues with whom I have worked on large scale structure in the universe: Jim Gunn, Martin Rees, Ed Turner, Sverre Aarseth, and Suke Bhavsar early on; Adrian Melott and Mark Dickinson, with whom I developed the spongelike topology idea; Andrew Hamilton, who derived a critical formula; David Weinberg, who implemented its use in many collaborations; Trinh X. Thuan and Michael Vogeley, with whom I worked on observational samples; Changbom Park, whose computer simulation proved cold dark matter could produce Great Walls; Barbara Ryden who worked on topology in rodlike samples, Wes Colley and Changbom Park, with whom I worked on the cosmic microwave background; Mario Jurić, who helped measure the Sloan Great Wall; Lorraine Hofstetter who helped make a picture of it; Juhan Kim, who, together with Changbom Park created the Horizon Run simulations; and Clay Hambrick, Yun-Young Choi, Robert Spearman and Prachi Parihar, who took part in our project to apply our topology technique to compare the large computer simulations with observations from the Sloan Survey. I thank Zack Slepian for his collaboration on a formula to characterize dark energy. Many of these people have followed this project for decades and have become lifelong friends. I treasure all these associations.

Preface

Galileo once said: “Philosophy [nature] is written in that great book which ever is before our eyes—I mean the universe.... The book is written in mathematical language, and the symbols are triangles, circles and other geometrical figures.” So it proved to be with the arrangement of galaxies in the universe. To understand it would require geometrical language.

When I was 18 years old, I discovered a group of intricate, spongelike structures made of triangles, squares, pentagons, or hexagons—some of which neatly divided space into two equal and completely interlocking regions. These were regular spongelike polyhedrons—figures composed of regular polygons whose arrangement around each vertex was identical. Being a teenager, when confronted with the ancient Greek wisdom that there were five, and only five, regular polyhedrons (the tetrahedron, cube, octahedron, dodecahedron, and icosahedron)—and that this had been proven long ago—I said, “Well, maybe not.” I made this my highschool science project and took it to my local science fair in Louisville, Kentucky. Surprisingly, this would later play a role in my own path to understanding the arrangement of galaxies in the universe.

Johannes Kepler was my inspiration. He had also questioned the ancient wisdom of the five regular polyhedrons. Kepler thought that the three regular polygonal tilings of the plane should be counted as polyhedrons also: the checkerboard, the hexagonal chicken-wire pattern, and triangles, six around a point, filling the Euclidean plane. Both the checkerboard and the cube were equally regular arrangements of polygons (even though one turned out flat and the other, three-dimensional). Kepler thought a checkerboard, for example, could be considered a new regular polyhedron—with an infinite number of faces. But Kepler didn’t stop there; he also recognized two new regular *starred* polyhedrons. One has faces that are five-pointed stars like those on the American flag. Isn’t a star just as regular as a pentagon? It has five points just like the pentagon, and is likewise made by drawing five equal-length lines connecting them. The only difference is that the lines are allowed to cross through each other! You just have to expand your mind a little to see five-pointed stars as regular. Kepler would take five-pointed stars as the faces of his new regular polyhedron. He had them cross through each other to form a three-dimensional star. Kepler understood that you could find new things by breaking the rules just a little. (See [Color Plate 1](#).)

Kepler was also fascinated with how one might use polyhedrons in astronomy. There were six known planets in his day. If you built a set of spheres whose radii marked the distances of each from the Sun, you would have six nested spheres. He thought that you might fit the five previously known regular polyhedrons between each of these spheres to explain the geometry of the solar system. In this he was wrong. And when more planets were discovered, the idea broke down completely. But when Kepler was told planets must have circular orbits, he thought to use elliptical orbits instead, and in this he was famously right.

But would my spongelike polyhedrons—which had geometries like a marine sponge, with many holes percolating through them—remain a mathematical fantasy, or would they even have any practical application in real-world astronomy? It turned out they had an application

in understanding galaxy clustering.

Edwin Hubble discovered that our Milky Way galaxy containing 300 billion stars was not alone in space. There were countless other galaxies just as big as ours. Furthermore, the whole assembly of galaxies was expanding, as I describe in [Chapter 1](#). But how exactly are these galaxies arranged in space? It was a puzzle that confronted astronomers. Galaxies congregated in clusters. [Chapter 2](#) tells how Fritz Zwicky famously studied this at Caltech. His work led American cosmologists during the Cold War to adopt a meatball model in which the high-density clusters floated in a low-density sea, as described in [Chapter 3](#). But the Russian school of cosmology favored a model where galaxies traced a giant honeycomb space with large empty isolated voids. This was a Swiss cheese universe ([Chapter 4](#)). I found that the new theory of inflation¹ ([Chapter 5](#)) was inconsistent with either of these pictures and required a spongelike structure in which great clusters of galaxies were connected by filaments of galaxies and great voids were connected to each other by low-density tunnels ([Chapter 6](#)).

Considering the theory of inflation and remembering those polyhedrons from my youth, I wrote a paper with Adrian Melott (University of Kansas) and Mark Dickinson (Princeton University) predicting that galaxies must be arranged on a giant cosmic sponge. The effort we made to verify this prediction became part of the larger story of how teams of observers embarked on heroic efforts to map the universe, as described in [Chapters 7, 8, and 9](#). These studies would give us vital insight into how the universe began. Astronomers began to chart the distribution of galaxies in space. Just as cartographers of the past mapped Earth, the cosmic cartographers began mapping our universe. Starting with surveys of a thousand galaxies, major surveys have now grown to encompass well over a million galaxies. Three-dimensional maps of the galaxies' distribution have now been made, and the structure they reveal has indeed proved to be spongelike. Great clusters of galaxies are connected by *filaments*, or chains of galaxies, in a spongelike geometry, while the low-density voids are connected to each other by low-density tunnels; this entire structure is now called the *cosmic web*. Fantastic filamentary chains of galaxies connecting great clusters have been found stretching over a billion light-years in length. These are the largest structures in the universe. Measuring one of them, called the Sloan Great Wall, landed Mario Jurić and me in the *Guinness Book of Records*—and we didn't even have to collect the world's largest ball of twine! I will explain how these largest structures in the universe arose as the great expanded fossil remnants of microscopic random quantum fluctuations in the early universe produced by inflation in the universe's first 10^{-35} seconds. This is supported by study of the fluctuations in the cosmic microwave background radiation left over from the universe's first moments ([Chapter 10](#)).

Not only do these structures illuminate the early universe, but they can also be used to forecast our future, as described in the final chapter. Will the universe keep expanding exponentially forever, as some models suggest, or will it ultimately coast along in a slow fashion? Or, will the universe end catastrophically with a Big Rip singularity in the next 15 billion years? A careful study of the cosmic web can help answer these questions. Distinguishing among these possible alternative futures is one of the highest-priority areas of research in astronomy today.

Ranging from a humble high school science project to mapping projects involving

hundreds of astronomers, this book will give you a window on how scientific research is done. It is a story of how unexpected connections can lead to new insights and how computer simulations combined with giant telescopic surveys have transformed our understanding of the universe in which we live. This is a semiautobiographical account focusing on my adventures but also emphasizing many of the people whose seminal ideas have influenced the field. I have had the good fortune to work with some of the greatest astronomers of our generation, investigating many of the aspects of this story in one way or another, from galaxy clustering, gravitational lensing, computer simulations, and mapping large-scale structures to inflation and dark energy. This book is told from my personal perspective as I meandered through the complicated web of talented people who fought for and finally won a better understanding of how the universe on large scales is arranged. A cosmic web, if you will.

The Cosmic Web

Hubble Discovers the Universe

It is fair to say that Edwin Hubble discovered the universe. Leeuwenhoek peered into his microscope and discovered the microscopic world; Hubble used the great 100-inch-diameter telescope on Mount Wilson in California to discover the macroscopic universe.

Before Hubble, we knew that we lived in an ensemble of stars, which we now call the Milky Way Galaxy. This is a rotating disk of 300 billion stars. The stars you see at night are all members of the Milky Way. The nearest one, Proxima Centauri, is about 4 light-years away. That means that it takes light traveling at 300,000 kilometers per second about 4 years to get from it to us. The distances between the stars are enormous—about 30 million stellar diameters. The space between the stars is very empty, better than a laboratory vacuum on Earth. Sirius, the brightest star in the sky, is about 9 light-years away.

The Milky Way is shaped like a dinner plate, 100,000 light-years across. We are located on this thin plate. When we look perpendicular to the plate, we see only those stars that are our next-door neighbors in the plate; most of the stars in these directions are less than a few hundred light-years away. We see about 8,000 naked-eye stars scattered over the entire sky; these are all our nearby neighbors in the plate, a tiny sphere of stars nestled within the thickness of the plate. But when we look out through the plane of the plate we see the soft glow of stars that are much farther from us but still within the plane of the plate. They trace a great circle 360° around the sky. Here we are seeing the circumference of the giant plate itself, as we look around the sky in the plane of the plate. We call this band of light the Milky Way. When Galileo looked at this band of light in his telescope in 1610, he found its faint glow was due to a myriad of faint stars—faint because they are so distant. With the naked eye we can see only their combined faint glow; we cannot resolve that glow into individual stars. It took a telescope to do that. For a long time, this constituted the known universe. Our galaxy appeared to be sitting alone in space—an island universe.

In 1918 our idea of our place in the universe started to change. Harlow Shapley discovered that the Sun was not at the center of the Milky Way but instead was about halfway out toward the edge. We were off center. Shapley felt like the new Copernicus. Just as Copernicus had moved Earth from the center of the solar system and properly placed the Sun at its center, Shapley moved the solar system from the center of the Milky Way to its place in its suburbs. Our position in the universe was looking less and less special. Shapley's monumental work did revolutionize our thinking about our place in the universe. He had the right to suppose that he had made what would be the most important discovery in astronomy in the twentieth century. *Time* would later put Shapley on its cover, on July 29, 1930. Shapley was the dean of American astronomers. But his great discovery of 1918 was soon

be eclipsed—twice—by Hubble.

Hubble studied the Andromeda Nebula, which had been thought by many, including Shapley, to be a gas cloud within the Milky Way. The word *nebula* comes from the Latin *nubes*, or “cloud,” denoting the fuzzy appearance of these objects. By careful observation with the new 100-inch telescope, Hubble discovered that Andromeda was actually an entire galaxy roughly the size of the Milky Way and very far away. Furthermore there were many other similar spiral-shaped nebulae seen in the sky, and these were *all* galaxies like our Milky Way! He classified galaxies by their shapes—elliptical, spiral, and irregular—like some botanist classifying microbes. He observed in different directions and counted the number of galaxies he found. There seemed to be an equal number in different directions. On the large scales the universe was homogeneous. There were fainter galaxies further and further away. We were just one galaxy in a vast universe of galaxies. This would have been discovered enough, but Hubble was not finished. He measured the distances to these galaxies. From spectra of these galaxies he could measure their velocities. He found that the further away a galaxy was, the faster it was moving away from us. The whole universe was expanding! That was astonishing. Isaac Newton had a static universe. Even Einstein, genius of curved spacetime, thought the universe must be static. The discovery that the universe was expanding was quite simply, astounding. It caused Einstein to revise his ideas about his field equations of general relativity—to backtrack on the changes he had made in them to produce a static cosmology. The expansion of the universe has profound implications.

If the universe were static, as Newton and Einstein had supposed, then it could be infinitely old. It would always have been here. This avoided Aristotle’s problem of first cause. If the universe had a finite age, however, then *something* must have caused it. But what caused *that*? Unless one is willing to accept an infinite regression of causes, there must be a first cause—but the question remains: what caused the first cause? An expanding universe brought this question back into play. If you played the tape of history backward, you would see all the galaxies crashing together in the past. There must have been something to start this expansion—a Big Bang—that began the universe. We now know this occurred 13.8 billion years ago. What caused this Big Bang? Astronomers following Hubble would work on that.

Hubble was the most important astronomer in the twentieth century. *Time* magazine put him on its cover on February 9, 1948. Behind him was a picture of the Palomar Observatory whose new 200-inch-diameter telescope could extend Hubble’s observations. He was the first person to observe with that telescope. Later *Time* would select Hubble as one of the 100 most influential people in the twentieth century (the only astronomer so honored). Despite the acknowledged importance of his discoveries, Hubble failed to get the American Astronomical Society’s highest award, the Russell Lectureship, given each year to an outstanding American astronomer for lifetime achievement. It reminds one of the Nobel Prize committee’s failure to award the Nobel Prize in Literature to Leo Tolstoy, even though they had several chances to do so before he died. The greatest people are often controversial. As with most groundbreaking discoveries, the whole story is more complicated, and interesting, than just the simple outline I have given so far. So let’s look into the story in more detail.

Shapley Blazes the Trail

Harlow Shapley had measured the position of the Sun in the Milky Way by using globular clusters. He measured their distances using RR Lyrae variable stars as objects of standard luminosity—*standard candles*. RR Lyrae stars are 40 to 50 times as luminous as the Sun and can be seen out to fairly large distances. They all have about the same intrinsic *luminosity*, the same wattage as lightbulbs, if you will. (The Sun, for example, has a luminosity of 4×10^{26} watts—equal to 4 trillion-trillion 100-watt lightbulbs.) If you saw an RR Lyrae star, you could figure out how far away it was by seeing how faint it appeared to be in the sky. It's like seeing a row of standard street lights extending down a street. They all have the same intrinsic luminosity, but the most distant ones will be fainter than the nearby ones.

Light emitted from a star spreads out in all directions, creating an ever-expanding sphere of light. Let's say you are 1,000 light-years from a star. The light that is passing you from the star is a spherical shell with a radius r of 1,000 light-years. The area of that sphere is $4\pi r^2$, or about 12 million square light-years. If you were 2,000 light-years away, the light would be diluted over an area of $4\pi r^2$ or $4\pi \times (2,000 \text{ light-years})^2$ —about 4×12 million square light-years. The new sphere is twice as big as the one before and has an area 4 times as great. This means that your detector—let's say your 200-inch-diameter telescope—will intercept $\frac{1}{4}$ as much radiation from the star as it would if it were only 1,000 light-years away from the star. If you are twice as far away, the star appears $\frac{1}{4}$ as bright. Brightness is measured in watts per square meter falling on your detector. Brightness diminishes like one over the square of the distance, a fundamental relationship called, not surprisingly, the *inverse-square law*.

Shapley could take repeated pictures of globular clusters of stars. A globular star cluster orbiting within the Milky Way would contain over 100,000 stars orbiting about the cluster's center of mass, like bees around a hive. Stars whose brightness varied from picture to picture could be identified as variable stars. Shapley could measure these stars' brightnesses as a function of time. He could recognize RR Lyrae variables by their periods of oscillation (the length of time between peaks in brightness, characteristically less than a day) and the amplitude of oscillation (the factor by which their brightness changed from brightest to faintest). Shapley could look at a particular RR Lyrae star and know its intrinsic luminosity. This was invaluable. Knowing its intrinsic luminosity, he could measure its apparent brightness in the sky and calculate its distance. The fainter it was, the farther away it would be. By measuring the apparent brightness of the RR Lyrae variables in a globular cluster, Shapley could measure the distance to the globular cluster itself. For more distant globular clusters, he used the brightness of the brightest stars in the cluster as a distance indicator, and for the most distant globular clusters, he used the clusters' angular sizes to estimate the distances: a cluster half the angular size was twice as far away.

Shapley measured the distances to many globular clusters, which orbit the center of the Milky Way galaxy in a nearly spherical distribution along paths that take them far above and below the flat "dinner plate" where most stars lie. Looking out above and below the galactic plane allowed him to find globular clusters at great distances, free of the confusing obscuring effects of interstellar dust in the plane itself. Shapley found that the 3D distribution of globular clusters in space was off-center relative to Earth. This result was puzzling: these globular clusters were orbiting the center of the Milky Way and should be centered on it, yet Shapley found more globular clusters (and ones that were further away) on one side of the sky than on the other. The distribution of globular clusters seemed centered on a point in the

direction of the constellation of Sagittarius about 25,000 light-years away. This point marked the center of the galaxy. Shapley had shown that *we* were not at the center of the Milky Way—but rather our solar system was about halfway between the center and the outer edge. This showed that the Sun was not at a special location at the center of the galaxy.

In 1920 Shapley had a famous debate with Heber Curtis about the nature of the spiral nebulae. In the period from 1771 to 1781 Charles Messier had made a catalog of nebulae. Through a small telescope they look like softly blurry patches of light and can be confused with comets. Messier was a comet hunter and wanted to make sure he didn't mistake these objects for new comets, so he took special note of them and cataloged them. These blurry objects actually include a number of different types of things. Some Messier objects (labeled by an M followed by their number in the catalog) are supernova gas ejecta (like the Crab Nebula M1) and some, like the Dumbbell Nebula (M27), are gas shed during the process of a star collapsing to form a white dwarf. Some are globular clusters (like M13), some are loose star clusters like the Pleiades (M45), many are gas clouds (star-forming regions) in the Milky Way, like the Orion Nebula (M42), and many more are actually external galaxies, like Andromeda (M31), the Pinwheel (M101), the Whirlpool (M57), M81, M87, and so on. The spiral nebulae, such as M31, M57, M81, and M101, were the subjects of the Shapley-Curtis debate. Their spiral shapes made them look somewhat like hurricanes seen from space. They had spiral arms winding outward from the center—like a pinwheel. Sometimes they were seen face-on, where they showed off circular shapes, and sometimes they were seen nearly edge-on, looking like dinner plates seen from the side. Were these gas clouds within the Milky Way or were they external galaxies like our own seen at great distances? Shapley maintained that they were gas clouds within the Milky Way. Curtis maintained they were external galaxies just like our own.

The proposals of famous astronomers and philosophers of the past came into the mix. The ancient Greek philosopher Democritus proposed that the band of light known as the Milky Way could actually be the light of distant stars (right idea—and in about 400 BC!). This idea would be confirmed by Galileo when he turned a telescope to the heavens. In 1750 Thomas Wright speculated that the Milky Way was a thin sheet of stars (right) but thought this was really part of a large, thin spherical shell of stars orbiting a dark center (wrong). Thus from a great distance he thought our galaxy should resemble a sphere of stars, a round blurry blob. Then he proposed that many of the faint nebulae we saw were entire galaxies like our own (right!). In 1755 William Herschel (the discoverer of Uranus) designated a subclass of nebulae he called “spiral nebulae.” That same year the preeminent philosopher of his day, Immanuel Kant, proposed that the spiral nebulae were actually galaxies like our own seen at great distances—he called them “island universes.” Curtis had these ideas on his side.

Shapley spent most of the time defending his recent determination of the enormous size of the Milky Way; he thought this result would make the predicted distances to the spiral nebulae seem ridiculously large if they were to be objects comparable to the Milky Way in size. Some novae (stars that suddenly flare in brightness by a large factor without exploding) were observed in spiral nebulae, and these had brightnesses comparable to other novae in the Milky Way, placing them firmly within our galaxy. Curtis mentioned this point again to himself. But in fact, these were *supernovae*, not novae at all but vastly more luminous stellar explosions that were actually just as far away as Curtis needed. Curtis's best argument came

from noticing that the spectra of the spiral nebulae looked like the spectra of star clusters, not those of gas clouds. The debate ended inconclusively. Most people in the audience probably left with the same views they had when they entered. In science, such questions are not settled by debates or by who scores more oratorical points. They are often settled by new and decisive data—which Hubble would soon be perfectly positioned to supply.

Hubble Changes the Game

Like most people who make important contributions, Hubble was blessed with both talent and luck. Born in Marshfield, Missouri, in 1889, Hubble held the high school high-jump record for the state of Illinois. He attended the University of Illinois and later went to Oxford as a Rhodes Scholar. Rhodes scholarships rewarded athletic as well as academic prowess. When he returned from England, he spent some time in my hometown of Louisville, Kentucky, living for part of that time in a quiet, genteel area of Louisville called the Highlands, where my mother and grandmother once lived. Hubble followed his father's wishes that he study law, but after his father's death, he turned to his true interests in science. He was a high school teacher for a while before going to graduate school at the University of Chicago, where he earned his PhD in astronomy; for his thesis research, he took photographs of faint nebulae. Here he had mastered the skill that would be needed to settle the Curtis-Shapley controversy. After a brief period of service in World War I, he returned to get a staff position at Mount Wilson. He was hired by George Ellery Hale. His good fortune was compounded. Yerkes Observatory, where he had done his doctoral work, possessed the largest refracting telescope in the world with a diameter of 40 inches. This was and still remains the largest refracting telescope ever built. It had a lens at the front, which brought light to a focus at the back, where an eyepiece was placed to view the image. Galileo's first telescope was a refracting telescope whose lens had a diameter of 1.46 inches. With this he was able to resolve stars in the soft band of light called the Milky Way. The Yerkes telescope was 40 inches in diameter, or 27 times as large in diameter. A lens is like a bucket to catch light, with a light-gathering power proportional to its area. (Put a bucket out in the rain; if it has twice the diameter, its opening area will be four times as large and will collect four times as much rain.) The Yerkes telescope had 27×27 , or 729, times the light-gathering power of Galileo's telescope. Since brightness falls off like the square of the distance, it should be able to discern stars 27 times more distant than those Galileo could see. Furthermore, long exposures using film gathered light over time and were more sensitive than the human eye. Hubble was by now an expert at taking just these kinds of pictures.

Now George Ellery Hale—telescope builder par excellence—enters. Hale, who had built the 40-inch Yerkes telescope, was just now finishing construction of the largest telescope ever—a reflecting telescope 100 inches in diameter—on Mount Wilson. A telescope with a 40-inch-diameter lens was about the largest of that type you could build. The lens had to be supported around its edge and began to sag in the middle if it was too big and heavy. But a reflecting telescope of the type invented by Isaac Newton let light come in the front and hit a big mirror in the back, where it was reflected back toward the front again. The light could then be directed via a small secondary mirror to a focus outside the tube where you would put the eyepiece. The big mirror was supported on its entire back surface and thus could be

larger. The 100-inch-diameter reflecting telescope was 2.5 times the diameter of the Yerkes telescope and able to detect individual stars 2.5 times further away. If Galileo could discern individual stars that were 25,000 light-years away in the Milky Way, the 100-inch telescope should be able to detect individual stars 1.6 million light-years away. With the advantage of long-exposure photographs, Hubble could extend this distance even farther.

Hubble arrived in Los Angeles in 1919 to take up his new job soon after the 100-inch telescope on Mount Wilson had opened for business. Hubble made good use of his unique opportunity. He took photographs of the Andromeda Nebula (M31). It was the spiral nebula with the largest angular size in the sky (modern photographs trace its diameter at 3° in the sky—6 times the angular diameter of the Moon.) It was, therefore, a good candidate for the closest spiral nebula. Hubble's photographs resolved it into stars. It was not a gas cloud. It looked like a fuzzy patch because it was made of faint distant stars. He made a sequence of photographs. Some of the brightest stars varied in brightness in a regular way over time. He could recognize them as Cepheid variables—stars whose luminosity varied periodically over periods ranging from days to months (and which were considerably more luminous than RR Lyrae stars). In 1908 Henrietta Leavitt, working at Harvard College Observatory, discovered a relationship between the period of oscillation of a Cepheid variable and its intrinsic luminosity. If you saw a Cepheid variable and measured the timescale of its periodic variation in brightness (in days), you could figure out its intrinsic luminosity (in watts) and therefore determine how far away it was by observing how faint it appeared to be in the sky. But the Cepheid variables Hubble found in the Andromeda nebula were *very* faint and therefore *very* far away, far outside the Milky Way Galaxy proper. The Andromeda Nebula was so far outside the Milky Way that given its angular diameter, it had to have a physical size of the same order of magnitude as the Milky Way. The Andromeda Nebula was itself a galaxy—just like the Milky Way. The Curtis–Shapley debate had been settled—Shapley was wrong, and Curtis was proved right. People like Immanuel Kant had speculated with good reasons that the spiral nebulae might be entire galaxies like our own, but now we knew. Hubble's evidence settled the case. It would turn out that Hubble's enormous distance estimate for M31 was actually an *underestimate*. But it made the point. M31 was indeed far outside our own galaxy.

The Andromeda Galaxy (M31) is actually 2.5 million light-years away. (I can call it a galaxy now rather than a nebula.) It is a disklike system about 120,000 light-years across. Our galaxy, the Milky Way, is a similar disklike system about 100,000 light-years across. If our galaxy were the size of a standard dinner plate (10 inches across), the Andromeda Galaxy (M31) would be another dinner plate 21 feet away. Light from the nearest star that we see today started on its way about 4 years ago. As you look farther away, you look further back in time. When you look toward the Milky Way's galactic center (in the constellation Sagittarius) 25,000 light-years away, you are seeing it not as it is now but as it was 25,000 years ago, about the time a child left footprints in the Chauvet Cave in France while viewing the cave paintings there. The light from the Andromeda Galaxy started on its way 2.5 million years ago, when our grandfather species from the genus *Australopithecus* walked the earth.

How can we visualize such large distances? Models can be helpful. At a scale of 1/billion, the entire Earth becomes a marble $\frac{1}{2}$ inch across. A billion is a big number. If Earth is a marble $\frac{1}{2}$ inch across, the Moon is a BB $\frac{1}{8}$ inch across, located 15 inches away. Fifteen inches

at a 1/billion scale is as far as human astronauts have ever gone—just 15 inches. The Sun, at this scale, is a beach ball 55 inches across, 500 feet away. The nearest star, Proxima Centauri, is a basketball 9 inches across, located 25,000 miles away. That's equal to the entire circumference of Earth, probably more than you drive your car in a year.

Let's shrink things by another factor of a billion, which shrinks Earth to a size smaller than an atom. At this scale of 1/billion-billion, Proxima Centauri is about the size of a hydrogen atom. The typical distance between stars is now about 1.6 inches. Imagine walking in a heavy snowstorm where the falling snowflakes are a less than a couple of inches apart. That is what our region of the Milky Way is like at a scale of 1/billion-billion. Go out at night, and you will see a snowstorm of stars. The Milky Way is about 2.5 miles across at this scale—about the size of a town. When we see the band of the Milky Way, we are seeing the distant lights of our town. Andromeda is another town 64 miles away, at this scale. Hubble was finding more and more galaxies stretching as far as telescopes could see. The typical distances between bright galaxies are about 24 million light-years—140 miles apart on our 1/billion-billion-scale model. Astronomers have seen galaxies as far as 13 billion light-years away—that's 76,000 miles away in our 1/billion-billion-scale model, in which stars are barely larger than atomic size. We are seeing these most distant galaxies as they were 13 billion years ago. This helps us visualize the vastness of the visible universe.

Slipher's Troublesome Redshifts

Meanwhile, Vesto Slipher was observing at Lowell Observatory in Flagstaff, Arizona, taking spectra of galaxies. Slipher found absorption lines in the spectra he took that were at wavelengths associated with particular elements. But he found them shifted slightly from their laboratory values. This is due to the Doppler shift. If a galaxy is moving toward us, succeeding wave crests of light are emitted at locations progressively closer to us as the galaxy approaches, crowding the wave crests together, shortening the wavelength of the light. Blue light has a shorter wavelength than red light, so this causes a "blueshift" in the spectral lines. If the galaxy is moving away from us, each subsequent wave crest reaching us is emitted at locations further and further away, and this stretches out the distance between wave crests. It causes a "redshift" in the spectral lines. The *redshift* z is defined as the fractional shift in the wavelengths of the spectral lines of a galaxy from the laboratory value $(\lambda_{\text{observed}} - \lambda_{\text{lab}})/\lambda_{\text{lab}}$. For small redshifts (much less than 1), such as Hubble was observing, z is approximately equal to the recessional velocity of the galaxy divided by the speed of light. (In general, the recessional velocity divided by the speed of light is $[(z + 1)^2 - 1]/[(z - 1)^2 + 1]$. As the red-shift approaches infinity, the recessional velocity approaches the speed of light, according to Einstein's theory of relativity.) We can experience the Doppler effect with sound waves when a train approaches blowing its whistle. As it approaches, we hear a high pitch (short-wavelength) sound, and after it passes the pitch becomes lower (long-wavelength) as the train moves away: WHEEEEEOOOOOOO.

Doppler shifts had already been used to measure the velocities of individual stars in the solar neighborhood. These velocities were on the order of 20 kilometers per second and showed some stars moving toward us and others moving away—not surprising, if these stars are moving with us on slightly different orbits within our galaxy. When Slipher measured the

Andromeda Galaxy, he found a blueshift corresponding to an approach velocity of 300 kilometers per second. This was an enormous velocity, roughly 0.1% the speed of light, much larger than that of individual nearby stars in our galaxy. Today we know that this high approach velocity toward the solar system results in part from the fact that the stars in our solar neighborhood have a mean rotational velocity about the center of our galaxy (about 220 kilometers/second), which happens to be sending us in more or less the direction of where Andromeda happens to be on the sky. Furthermore, the Andromeda galaxy is actually falling toward the Milky Way because of their mutual gravitational attraction. By measuring the differential shift in the spectral lines across the face of an individual galaxy, Slipher was the first to prove that the spiral nebulae were rotating. Slipher continued taking spectra of galaxies and found to his surprise that almost without exception (Andromeda being one) they had redshifts. In general, galaxies were moving away from us. In 1917 he published a table of redshifts. The average recessional velocity of the galaxies in his table was 570 kilometers/second. Astonishing—and unexpected. As he looked at ever fainter (more distant) galaxies, the average recessional velocity had risen from 400 kilometers/second in 1915 to 570 kilometers/second by 1917. The effect was getting more dramatic. On this basis, John Peacock (2013) has argued that Slipher should be given credit for the discovery of the expansion of the universe—because he found so many redshifts, indicating that other galaxies were moving away from us. Peacock has noted that Slipher's redshifts, because they were so large, identified the spiral nebulae as objects outside our galaxy. Slipher did consider the idea that the spiral nebulae might be scattering, but he rejected the notion because they also seemed clustered. Ultimately, Slipher thought galaxies might be moving at high individual velocities edgewise through space, like thrown Frisbees—in that surmise he was incorrect. Slipher deduced that the solar system had an individual velocity of about 700 kilometers/second relative to the mean motion of all the galaxies he saw. The modern value for this is 384 kilometers/second. Slipher's work on redshifts was fundamental and set the stage for what Hubble was able to do later. In addition, as director of the Lowell Observatory, Slipher hired Clyde Tombaugh and started him on the project that would result in the discovery of Pluto. For his contributions, Slipher was awarded the Gold Medal of the Royal Astronomical Society in 1932.

Einstein Has His Say

Theory enters here. In 1915, after 8 years of concentrated effort, Einstein worked out the correct field equation for his theory of general relativity. This theory explained gravity in a revolutionary way, as the result of curved spacetime. Einstein's equation showed how the "stuff" of the universe (matter, energy and pressure) cause spacetime to curve. The right side of the equation describes the mass-energy density and pressure associated with stuff (matter and radiation) at a point. The left side of the equation tells us how spacetime is curved at that point.¹ Particles follow the straightest trajectories they can in the curved space and time. In the same way, a plane follows a great circle trajectory when traveling between two points on Earth. A plane traveling on a straight-line trajectory from New York to Tokyo will pass over northern Alaska. Stretch a string taut between the two cities on a globe to confirm this. The trajectory looks curved on a flat Mercator map of Earth, but on the curved surface of the

globe it is the straightest trajectory you can draw—it is called a *geodesic*.

Einstein could then work out the geodesic trajectories of planets. They differed slightly from those Newton had found. The planet Mercury no longer followed the simple elliptical (Keplerian) path that Newton's theory of gravity predicted. The effects were largest close to the Sun. Einstein predicted that the elliptical shape of Mercury's orbit should slowly rotate as Mercury continued to circle the Sun. This rotation of the orbit amounted to 43 seconds of arc per century. A second of arc is $1/3,600$ of a degree—so this is a tiny amount of orbital rotation in a century. Nevertheless, astronomers had already measured just this amount of anomalous rotation in Mercury's orbit, an effect that Newton's theory was unable to explain. When Einstein did this calculation, he said he was so excited it gave him palpitations of the heart. When his prediction of 43 seconds of arc per century matched the exact amount of unexplained rotation astronomers had already observed, he was overjoyed.

Einstein then calculated how much light itself should bend as it passed near the limb of the Sun. According to his theory it should be deflected by 1.75 seconds of arc. If particles of light were attracted by gravity in the same way that massive particles were in Newton's theory, the deflection would be only half that—0.87 seconds of arc. The effect could be tested during a total eclipse of the Sun, when the Moon blocks the Sun's bright surface, allowing background stars to be observed near it. In 1919 Sir Arthur Eddington's British expedition took photographs of stars near the Sun during a solar eclipse and compared them with the positions of those stars on photographs taken 6 months later, when Earth had moved so the Sun was nowhere near those stars in the sky. Deflections of 1.98 ± 0.30 and 1.61 ± 0.30 seconds of arc were observed during the eclipse from two different locations, in agreement with Einstein's value within the observational errors (± 0.30 seconds of arc) and in clear disagreement with Newton's value. Newton's account of gravity was overthrown. This was the "play of the century" in science. On the day he learned of the eclipse results, Einstein wrote a touching note to his mother, saying: "Good news today." The results were publicly announced at a joint meeting of the Royal Society and the Royal Astronomical Society. J. J. Thomson (the discoverer of the electron) pronounced the result "the most important result obtained in connection with the theory of gravitation since Newton's day." At that moment Einstein moved up to Newtonian stature. The Einsteinian deflection was quickly confirmed by W. W. Campbell and R. Trumpler, in the 1922 solar eclipse; they found a deflection of 1.82 ± 0.20 seconds of arc. Importantly, it has been confirmed with higher and higher accuracy ever since.

In 1916 Karl Schwarzschild found an exact solution to Einstein's equation for a point mass. We know this today as the *black hole solution*. In 1917 Einstein applied his equation to cosmology. He found he could not produce a static solution. Newton had a static universe of stars filling infinite space uniformly, with the gravitational forces on each star on average canceling out. Such a universe could be infinitely old and escape the question of first cause. Einstein in 1917 knew that the individual velocities of stars were small, of order 200 kilometers/second, much less than the velocity of light, and moving randomly. This suggested to him a static universe. So, he added a term to his field equation of General Relativity.² The new term was called the *cosmological constant*. It preserved the desirable property of the original equations that energy was conserved locally (in small regions), and the new term was so tiny it did not interfere with the orbit of Mercury or the light bending appreciably.

Primarily, it provided a repulsion term that balanced the average gravitational attraction of the stars for each other, allowing a static model of the universe. In his 1917 paper he argued that such a static model was required because of the small velocities of the stars (relative to the speed of light). These, of course, were just stars in our solar neighborhood in the Milky Way. In the Einstein universe, the volume of space was finite and curved but had no edges. It was like the surface of a higher-dimensional sphere called a *3-sphere*. Just as a circle has a finite circumference and a sphere has a finite surface area, Einstein's Time 3-sphere universe had a finite volume. If you started off in your spaceship on a voyage in Einstein's static universe and steered as straight a course as you could, you would return to your home planet after having circumnavigated the entire universe—just as you can circle Earth's surface and return to where you started. Because Einstein's universe was static, its volume was unchanging with time. [Figure 1.1](#) shows a spacetime diagram of the Einstein static universe. It shows the dimension of time vertically, with the future toward the top. One dimension of space is shown horizontally. The Einstein static universe spacetime looks like the surface of a cylinder. The static 3-sphere universe is depicted as a circle whose circumference is constant with time. Stack up a bunch of circles (all the same radius) representing the 3-sphere universe at different instants and you get a cylinder. The only thing real in this picture is the cylinder itself. Forget the inside and outside.

Figure 1.1. Spacetime diagram of the Einstein Static Universe. We are showing only one dimension of space (around the circumference of the cylinder) and the dimension of time (the vertical direction, future toward the top). Worldlines of stars (or galaxies) are straight lines (geodesics) going straight up the cylinder. The circumference represents the circumference of the surface of a higher-dimensional spherical balloon (a 3-sphere) whose radius is unchanging with time. The only real thing is the cylinder itself—the inside and outside have no significance. (Credit: J. Richard Gott, *Time Travel in Einstein's Universe*, Boston: Houghton Mifflin, 2001)

That same year, 1917, Dutch mathematician and physicist Willem de Sitter found an exact solution to Einstein's field equation, including Einstein's new cosmological constant term but having no matter in it at all. This was an empty universe—no stars, no galaxies, just empty curved space. (Why should we be interested in such a universe? Because the real universe is of rather low density and so might roughly approximate an empty universe in the limit.) De Sitter's universe looked static as well and seemed to cover only half of a higher-dimensional 3-sphere—as if you had cut Einstein's static universe in half and then thrown half of it away. If you sat at the “north pole” of this universe, you could see down only to its “equator.” De Sitter proposed that antipodal points in spherical universe be identified as identical points—if you had a replica of yourself living at the south pole. That way, the universe you saw (north of the equator) really included all the objects in the universe. The de Sitter universe would thus have half the volume of the comparable Einstein static universe. You would see objects that lived closer to the equator aging in slow motion and emitting light waves in slow motion. If their atoms emitted light at a certain frequency, you would see it at a slower frequency—and a longer wavelength. Thus, in de Sitter space, distant objects showed

redshifts. This might explain Slipher's redshifts. These were gravitational redshifts, caused by a photon of light losing energy and increasing in wavelength as it fights its way out of a deep gravitational well. This effect is predicted by general relativity. Clocks on Earth tick a tiny bit slowly relative to those in interstellar space. Einstein, in his work on the photoelectric effect, showed that electromagnetic waves (light) are composed of photons whose energies are inversely proportional to their wavelength. When we send a photon into the sky, it loses energy as it climbs against Earth's gravitational field, and its wavelength increases. (GPS systems using satellites have to take this effect into account when they calculate your position.)

But de Sitter's static coordinate system was incomplete and gave a false impression. It is like the story of a blind man examining an elephant; if he touched only its trunk, he might pronounce that an elephant was most like a fire hose. [Figure 1.2](#) shows our modern understanding of de Sitter spacetime.

It is a 3-sphere universe that starts off with infinite size in the infinite past, contracts to a minimum radius at a "waist" in the center, and then reexpands. It is the gravitational repulsive effect of the cosmological constant that halts the contraction and causes the subsequent expansion. De Sitter spacetime looks like a corset. The waist appears as a circle. This represents the circumference of the 3-sphere universe at the time of its minimum size. The "north pole" is the point at the far left edge of this circle. But the north pole is not just a point that lasts for an instant. It stays around forever. If you live there, your worldline—your path through spacetime—is the vertical corset stay at the far left. De Sitter's static coordinate system, trails after you like a flock of geese following after a leader. The coordinate system covers only the one quadrant of de Sitter spacetime next to the north pole corset stay.

Figure 1.2. Modern understanding of De Sitter spacetime. Diagram shows one dimension of space (around the circumference) and the dimension of time vertically, future toward the top. De Sitter spacetime looks like a corset with a narrow waist at the middle. The horizontal circular cross sections show the size of the 3-sphere universe as it contracts and then expands. The vertical “corset stays” represent possible geodesic *worldlines* (paths through spacetime) of particles. Put a large X through the center of the figure—De Sitter’s 1917 coordinate system covered only the left quadrant; leaving out top, bottom, and right quadrants. It made the spacetime look static, but actually it is dynamical, as depicted here. (Credit: J. Richard Gott, *Time Travel in Einstein’s Universe*, Boston: Houghton Mifflin, 2001)

Actually, de Sitter space was a complete spherical universe. It was expanding at late times, which caused distant galaxies to have redshifts. It was a strange universe.

Astronomers at that time were asking themselves if de Sitter space was a useful model for our universe. A piece of Princeton lore (which I heard as a graduate student) was that Henry Norris Russell once asked Harlow Shapley if the Slipher redshifts could be due to the de Sitter effect. No, Shapley reportedly replied, that was impossible, since the globular clusters [Shapley erroneously thought] were at much larger distances than the spiral nebulae, and they showed no redshifts at all! Without proper distances, Shapley found Slipher’s redshifts did not even convince him that the spiral nebulae were outside the Milky Way.

In 1922, Alexander Friedmann, in Russia, found an exact solution to Einstein’s original equations *without* the cosmological constant. This was a dynamical solution—not static. Like the Einstein static universe, its shape was the surface of a higher-dimensional sphere—a sphere, but its radius changed with time. It started at zero size with a Big Bang. It then expanded rapidly. Galaxies would be like pennies taped to the surface of a balloon: as you
